Investigation of the initial deposition steps and the interfacial layer of Atomic Layer Deposited (ALD) Al₂O₃ on Si

Georgios P. Gakis, Constantin Vahlas, Hugues Vergnes, Sandrine Dourdain, Yann Tison, Hervé Martinez, Jérôme Bour, David Ruch, Andreas G. Boudouvis, Brigitte Caussat, Emmanuel Scheid

1. Introduction

During the last two decades, the constant shrinking of electronic devices requires the production of conformal ultra-thin film structures, able to answer to the demands of the microelectronic industry [1]. The high k gate oxides used for the transistor gate stack in microelectronic devices need to be highly uniform and pinhole-free on the semi-conductor surface (Si) to prevent leakage current [1]. Within this context, the Atomic Layer Deposition (ALD) process [2] has emerged as the appropriate process to produce such films.

ALD is a film deposition technique based on the sequential use of gas-solid reactions [3]. The advantage of ALD relies on the self-saturating chemisorption of the reactants on the surface, which ensures a high control over the thickness of the deposited film [2]. A wide variety of materials has been deposited by ALD [3], making it a powerful tool in thin film deposition technologies.

One of the most studied ALD processes is the deposition of Al₂O₃ films, using tri-methyl aluminum (Al(CH₃)₃, TMA) and H₂O vapor as a metal precursor and oxidant source, respectively [3]. Al₂O₃ is a favorable candidate to replace SiO₂ as a dielectric layer as it has a higher dielectric constant and has a similar band gap [4]. A great number of works has been published on this ALD process, dealing with the deposition process [5-7], reaction mechanisms [8-10], reaction kinetics [11-13], as well as the ALD reactor dynamics [13-15].

However, even for these well-known ALD Al₂O₃ films, the deposition is non ideal. Specifically, during the first stages of Al₂O₃ ALD from TMA and H₂O, an induction period has been reported on HF-cleaned Si surfaces [16,17]. This has been attributed to an island growth of the conformal and continuous Al₂O₃ films, making difficult the deposition of ultra-thin, i.e. thinner than 3 nm, films on clean silicon. This regime has been studied both experimentally [16,18,19], and theoretically, with the use of computational models [16,17,20]. The analysis of the nucleation and
growth steps during the first ALD cycles, however, remains crucial for
the understanding of the inhibition mechanisms and thus the deposition
of conformal, nanometric thin films.

In addition to the induction period and the non-layer by layer
growth, during the first steps of the ALD process, an interfacial layer is
formed between the deposited alumina film and the Si substrate. This
interface is of great importance, as it can affect the electrical properties
of the dielectric film [21], and thus its applications. Even though this
interfacial layer is thicker for films grown with O₂ or O₃ plasma
[21,22], it is nonetheless formed when using H₂O as the oxygen source
[4,21–24]. The mechanisms involved are not well understood. Nau-
mann et al. [24] reported an interfacial layer containing SiO₂ and OH,
formed during the initial deposition steps. According to their work, the
OH groups formed during the initial stages of deposition enhance
substrate oxidation. After the ALD layer formation, O diffusion through
alumina leads to further interfacial oxide growth. Renault et al. [4]
reported a thin interface, consisting mainly of SiOₓ in multiple oxida-
tion states. They assigned interfacial oxidation to Al-OH groups that
serve as bulk defects and enhance Si oxidation and O diffusion. Inter-
facial oxide regrowth during thermal annealing has also been reported
[4,24,25]. Gosset et al. [25] showed the presence of Al, C, OH and H in
the interface, thus showing the complex chemical composition of this
layer. This interface has a negative impact, as it affects the electrical
properties of the deposited structure, exhibiting a low dielectric con-
stant and high leakage current for thin films below 4 nm [21], thus
limiting the interest for potential applications of such films.

In this work, we deposit Al₂O₃ films via ALD, using TMA and H₂O as
reactants, in a commercial ALD reactor. The films, obtained after var-
ious numbers of cycles, are characterized by X-ray Reflectivity (XRR),
Transmission Electron Microscopy (TEM) and Scanning Transmission
Electron Microscopy in Bright Field mode (BF-STEM). As a substrate
inhibited growth is observed during the first ALD cycles, we develop a
computational model, inspired by the work of Nilsen et al. [20], si-
mulating the island growth on the surface. The island growth for the
ALD of alumina has been studied theoretically before [16,17], but with
phenomenological models. The present model is based only on geo-
metric principles, as that of Nilsen et al. [20] and takes into account the
three dimensional aspects of the growth. Information about the growth
regime, island coalescence, and surface concentration of nucleation
sites are extracted from this analysis.

Information about the interfacial layer formation as a function of the
number of cycles and film deposition is also drawn from the ex-
perimental analysis, illuminating certain aspects of its formation me-
chanisms. The depth profile of the deposited film and its interface in
terms of elemental composition is studied using Energy Dispersive X-
ray spectroscopy (EDX), X-ray Photoelectron Spectroscopy (XPS) and
Time of Flight Secondary Ion Mass Spectrometry (ToF-SIMS) char-
acterizations, yielding information on its chemical nature. The results
about the interfacial layer formation and its composition can serve as
valuable information for restricting its formation by applying adequate
surface pre-treatments for Si.

2. Materials and methods

The Al₂O₃ films were deposited using a commercial Veeco® Fiji
F200 ALD setup, on 100 mm diameter Si (100) wafers. The wafers were
pretreated by deionized (DI) water rinsing, followed by dipping in a 5% HF
solution for 1 min, in order to remove the native oxide on the Si
surface, and a final DI water rinsing. After the pretreatment, the wafer
was dried and immediately loaded into the chamber, which was
pumped out to its base pressure (10⁻⁴–10⁻⁵ Torr) for 10 min, then to
the base pressure of the ALD process (0.072 Torr) with Ar nominal flows
for 5 min.

The TMA pulse time was set to 0.025 s, while the water pulse was
0.1 s. The two reactant exposures were separated by an Ar purging step
of 5 s. The pulsing and purging times being set, the isolation valve of the
capacitance manometer was closed. The number of cycles used varied
from 5 to 550. The substrate temperature was kept at 300 °C, for all
samples. This process recipe has been studied before [13] and yields a
steady state growth per cycle of ~0.1 nm/cycle. For more information
about the deposition mechanisms and the process setup, the reader is
referred to our previous works [13,14].

The thickness of the deposited films was measured by two means.
Firstly, for some samples we used Transmission Electron Microscopy
(TEM) and Bright Field Scanning TEM (BF-STEM) with a 200 kV JEOL
JEM-ARM200F Cold FEG microscope, coupled to an Energy-dispersive
X-ray spectroscope (EDX), which was used for the chemical character-
ization of the films. The cross section preparation was done by Focused
Ion Beam (FIB) milling in a FEI Helios Nanolab 600i dual beam SEM/FIB.
For the TEM and STEM analysis, the Al₂O₃ film was capped by a
30 nm carbon layer using an electron beam, followed by a 3 µm Pt layer
deposited with an ion beam.

Secondly, we systematically used X-ray reflectivity measurements,
which were carried out using a Bruker D8 diffractometer with Cu Kα1
(0, = 0.154056 nm) radiation. All measurements were carried out in
θ – θ geometry for which the sample was kept fixed during the mea-
surements. Experimental curves were fitted using reflex software [37]
based on the Parratt algorithm to obtain the thickness and the electron
density profile of the prepared layer.

In order to analyze the film composition as a function of the film
depth, dynamic SIMS analysis was performed using a ToF SIMS V
IOnToF, Münster, Germany). For the depth profile measurement, a
25 keV pulsed Bi/s cluster ion source delivering 0.31 pA of target
current was used for the analysis while a 3 keV Cs+/ source was oper-
ated for the sputtering with 20 nA target current. The sputtered crater
size was 250 µm × 250 µm and only a 100 µm × 100 µm area in the
middle was analyzed. To limit the charging effect, an electron flood gun
was used. The data were recorded in positive mode and ions combined
with a Cs atom were followed for the depth profile.

X-ray photoelectron spectroscopy (XPS) was performed in a Thermo
ESCALAB 250 Xi XPS system in order to study the chemical nature of
the film bulk and interface. XPS was performed using an Al Kα source
(1486.7 eV) with a 20 eV pass energy, while the XPS binding energy
scale was calibrated by the adventitious C 1s peak at 285.0 eV. Curve
fitting has been performed using CasaXPS©; for 1s core peaks (O 1s, C
1s), a single peak has been used for each chemical environment while
doublets have been used for 2p core peaks (Si 2p, Al 2p), accounting for
spin-orbit coupling.

2.1. Island growth model presentation and validation

The computational model for island growth is inspired from the
works of Nilsen et al. [20] and is based on geometric principles. The
islands are assumed to be hemispherical due to the amorphous nature of
the films [20], and grow on discrete nucleation sites. The nucleation
sites are uniformly distributed, forming a square surface lattice. Due to
the uniform distribution, the analysis is simplified to only one of the
squares of the lattice, by imposing periodic boundary conditions.

The size of the squares from which the surface lattice is composed
can be deduced from the nucleation density, N₀, which is the surface
concentration of nucleation sites. If A is the area of the squares and b is
their side length, then:

\[
A = b^2 = \frac{1}{N_0} \tag{1}
\]

\[
b = \sqrt{\frac{1}{N_0}} \tag{2}
\]

The thickness is computed as a mean thickness of the island over the
whole square area A:
The island growth is divided into three regimes, illustrated in Fig. 1. The first regime is the free island growth regime, where the islands grow in hemispheres within the square lattice. The starting point for the second regime, island coalescence, is the moment when the island coalescence starts. The third regime, continuous film growth, starts when the whole surface is covered by the deposited film, hence when the film is continuous on the whole surface lattice. As the islands continue to grow and coalesce, this regime leads the ALD process to its steady state, where linear growth is obtained as a function of the ALD cycles.

The three regimes are taken into account in the geometric model. The critical island radius value for the transition from the first regime to the second is:

$$r_{1 \rightarrow 2} = \frac{b}{2}$$

While the critical value for the transition for the second regime to the third is:

$$r_{2 \rightarrow 3} = \frac{\sqrt{2} \cdot b}{2}$$

Hence, the volume of the islands, is computed as follows:

If \( r_n \) is the island radius at the nth cycle:

For

$$r_n \leq r_{1 \rightarrow 2}$$

the island volume is equal to the volume of the hemisphere:

$$Volume = \frac{2\pi r_n^3}{3}$$

For

$$r_{1 \rightarrow 2} \leq r_n \leq r_{2 \rightarrow 3}$$

the island volume is equal to the volume of the hemisphere, minus four times the equivalent volume of half of a top spherical cap.

$$Volume = \frac{2\pi r_n^3}{3} - 4 \cdot \frac{\int_0^{r_n} \pi (r_n^2 - z^2)dz}{2}$$

For

$$r_n \geq r_{2 \rightarrow 3}$$

the film is continuous, and the island occupies the whole square. The volume of the island is:

$$Volume = \int_{r_n/2}^{r_n/2} \int_{r_n/2}^{r_n/2} \int_{\sqrt{r_n^2 - x^2 - y^2}}^{0} dz\, dx\, dy$$

Using the above model, the Growth per Cycle (GPC) evolution can be computed as a function of the number of ALD cycles, as follows:

$$GPC_n = Thickness_n - Thickness_{n-1}$$

The island radius at the nth cycle is given by:

$$r_n = r_{n-1} + \Delta r,$$

where \( \Delta r \) is the radius increase during each ALD cycle. Its value is equal to the GPC at the steady ALD regime, where the thickness is a linear function of the ALD cycles. This value is easily accessible by experimental measurements, once the steady ALD regime is reached. The initial island radius prior to ALD deposition, \( r_0 \), is a model parameter. Although it is usually taken as zero, it is nonetheless included for the generality of the model. Surface functionalization can lead to the presence of nucleation sites with a radius of some number of Å.

The computational model has two fitting parameters, which are the nucleation density, \( N_d \) and the initial radius of the islands, \( r_0 \). The value of \( r_0 \) represents the apparent radius of a surface nucleation site. As nucleation sites are usually surface defect sites, \( r_0 \) varies from zero to some number of Å. Once this value is set, by tuning the values of \( N_d \), an estimation of the surface concentration of nucleation sites can be derived, by fitting the model results to experimental data.

To demonstrate the validity of the model, we have compared its results with literature experimental data. It is worth noting that the model is independent of the deposited material, as long as it is amorphous and the island growth indeed occurs. This is why we present a comparison between model predictions and literature data, for the ALD of Al2O3 on Si–H [19], PtO2 on Si with native SiO2 [36], and W on SiO2 [34] in Fig. 2. For all cases in Fig. 2, the initial radius value, \( r_0 \), was set to zero. The \( \Delta r \) values are taken from the slope of the thickness once the linear ALD regime is obtained.

The good agreement between model predictions and literature data in Fig. 2 proves that the model can be used to analyze the deposition during the first cycles, and extract an estimation of the nucleation density. The growth mode can be predicted and characterized, without using any chemical reactions, but only geometrical principles, using two fitting parameters. Hence, the initial growth evolution can be explained by geometrical aspects of the film growth, without assuming an increasing surface reactivity with the number of ALD cycles. The growth regimes during the first steps of deposition can be separated and studied, as well as the transition between them. The nucleation density fitted for the data in Fig. 2 varies between 0.06 and 0.09 groups/nm². Nucleation densities derived from the fitting of such models to experimental measurements have previously been assigned to surface defect sites [16,20].
3. Results and discussion

3.1. Evolution of Al₂O₃ growth

The ALD films using various numbers of cycles were characterized by XRR in order to determine their thickness. The XRR data were fitted using a matrix model (Parratt formalism [37]) by considering a fixed density of Al₂O₃ in the deposited layer in order to recover its thickness. XRR data and calculated curves are shown in Fig. 3a. The derived deposited thickness is plotted in Fig. 3b as a function of the number of ALD cycles, along with the predictions of the island growth model.

The predicted evolution of the GPC and the growth regimes are shown in Fig. 3c. Results of Fig. 3b show that an induction period occurs during the initial stages of Al₂O₃ ALD on H-terminated Si. This behavior has been previously reported by Puurunen et al. [16,17] for the ALD of alumina on Si–H. This is due to the low reactivity of the Si–H species towards ALD reactants [30,35]. This low reactivity prevents TMA and H₂O from depositing on the surface.

Nucleation is reported to start on surface defect sites [16,17,30], such as surface OH groups or oxygen bridges that have not been totally removed during the substrate cleaning process. These defect surface species are reactive towards the ALD reactants, contrary to the Si–H species. Then, subsequent exposure leads to preferential deposition of the reactants on the already deposited material and its adjacent surface sites [16,30], thus leading to the formation of islands, as assumed by the island growth model. The good agreement between the island growth model and the XRR measurements shows that indeed the surface inhibited growth and preferential deposition lead to an island growth regime during the first deposition steps.

The fitting of the model yields an estimation of the surface concentration of the initial nucleation sites, i.e. the surface defect sites. The GPC at the steady ALD regime is 0.1 nm/cycle, which is consistent with our ellipsometry measurements and the mechanistic surface kinetics model we presented in our previous work, for the same ALD reactor [13]. This value is assigned to OH groups, it is 1.27% of the surface concentration of OH groups on silica at 300 °C, as reported by Haukka and Root [33]. This means that the HF cleaning efficiently removes the native oxide layer.

As the number of cycles increases, island growth and coalescence occurs. The different regimes are dictated by the state of the growing islands and are shown by the characteristic evolution of the GPC in Fig. 3c. Islands growing freely on the surface increase the available surface for deposition and hence the GPC is enhanced. This occurs until \( r = r_{1,2} = \frac{1}{2} \), as described in the previous section. In the present case, this happens after 18 ALD cycles. From the moment the islands start to coalesce, the surface available for deposition starts to decrease, until the formation of a continuous film. This happens when \( r = r_{2,3} = \frac{3}{4} \), which in the present case is after 25 ALD cycles. This prediction is in agreement with the experimental observations of Puurunen et al. [16]. From then onwards, the coalescence continues, decreasing the surface available for deposition, and thus the GPC, until layer by layer growth is reached, where the GPC becomes constant. The above analysis shows that at least 25 ALD cycles must be performed, in order to obtain a continuous Al₂O₃ film. This approach also shows that the evolution of the film growth can be explained by the geometric
aspects of growth, without assuming an increasing surface reactivity with the number of ALD cycles.

3.2. Morphological characterizations of Al₂O₃ films

The obtained Al₂O₃ films after different numbers of ALD cycles were characterized by TEM and BF-STEM. The bulk of the Al₂O₃ is distinguished from the Si substrate and the C capping layer. The films are all amorphous, confirmed by fast Fourier Transform (FFT) analysis of the TEM images, in contrast to the crystalline Si substrate. The TEM analysis of the film grown after 200 ALD cycles is shown in Fig. 4.

It is seen that the Al₂O₃ film is uniform and conformal. It is distinguished by a darker contrast than both the Si substrate and the C capping layer. The ALD layer has a thickness of ∼20.3 nm, yielding a mean GPC of ∼0.1 nm/cycle. The GPC computed from our surface kinetic model [13], as well as the GPC derived from the island growth model and the XRR measurements are consistent with this measurement. This GPC of ∼0.1 nm/cycle was also measured for the sample deposited using 550 ALD cycles.

An interfacial layer between the ALD grown film and the Si substrate is also observed in Fig. 4 as a bright-contrast layer. Literature reports conclude that this layer is either observable [26–28] or not observable [22] for the TMA + H₂O process. This interface is reported to mainly consist of Si oxides [4,24,25], formed by interdiffusion of Si and O species. To further investigate the interfacial layer morphology and film evolution, TEM and BF-STEM images of the Al₂O₃ films formed after 5, 20 and 200 ALD cycles are shown in Fig. 5. The films deposited using 5 and 20 ALD cycles were characterized by STEM in bright-field, for a more clear distinction of the interface.

For the sample deposited using 5 ALD cycles (Fig. 5a), the BF-STEM micrograph shows no clear distinction between an Al₂O₃ layer and the interface. According to the island growth model and the results of Puurunen et al. [16], the deposition is still in the nucleation period, where island growth takes place. A layer with a varying darker contrast could be argued to be present between the C layer and the brighter contrast interfacial oxide layer. It could be attributed to islands closely behind each other in the cross-sectional sample, giving the appearance of a continuous layer [16]. The layer's varying contrast consolidates this explanation. For this sample, a combined layer of ∼1.6 nm is measured between the crystalline structure of the Si substrate and the brighter contrast of the C layer.

For films deposited using 20 and 200 cycles (Fig. 5b and c, respectively) the interfacial layer is clearly visible and can be distinguished from both the Si substrate and the Al₂O₃ layer. The measured Al₂O₃ and interface layer thicknesses by the TEM and BF-STEM analysis are summarized in Table 1 for all samples, as for a 550 cycles sample (not shown in Fig. 5).

An interface of ∼1.8 nm was measured for the 20 cycles sample (Fig. 5b), while the 200 cycles sample showed an interface of ∼2 nm (Fig. 5c). The interfacial layer thickness is close for both samples, which shows that between 20 and 200 cycles, little or no Si oxidation took place. So, after a certain thickness, the Al₂O₃ layer serves as a diffusion barrier for Si and O species. This has been previously reported for the Al₂O₃ deposition on Cr surfaces, where a thin thermal ALD Al₂O₃ layer was found to serve as an efficient diffusion barrier to prevent Cr oxidation during subsequent plasma enhanced ALD [29].

The 20 cycles sample (Fig. 5b) also exhibited a slightly higher roughness on its interface with the C capping layer. This is attributed to the end of the island growth mode. According to the island growth model, the island coalescence has started at that point and a continuous layer is obtained only after 25 cycles. The varying contrast along the layer in Fig. 5b, could be assigned to this phenomenon. In their work, Puurunen et al. [16] revealed the Al₂O₃ islands on Si, by in situ depositing an amorphous Si layer on top of their samples. When the Al₂O₃ layer was not continuous, the deposited Si aligned epitaxially on the Si substrate, thus making the Al₂O₃ islands visible [16]. They estimated that the film becomes continuous between 20 and 30 cycles, in agreement with the predictions of the island growth model presented here.

3.3. Chemical characterization of the Al₂O₃ films

The deposited films were characterized by XPS, in order to study the chemical nature of the deposited films and their interfaces with Si. The Al 2p, O 1s and Si 2p spectra are presented in Fig. 6, for ALD films deposited using 10 and 50 ALD cycles. The intensity scales have been adjusted to highlight the different features of the spectra.

Fig. 6 shows that Al is detected on the surface even for the 10 ALD cycles sample. Although the intensity is lower than for the 50 cycles sample, the peak position is the same. The main peak is located at 74.8 eV and can be simulated by a doublet peak (Al 2p₃/₂: 74.8 eV, Al 2p₁/₂: 75.24 eV), showing the presence of O-Al-O bonds. The Al 2p peak for both samples could also be fitted by a single symmetrical peak at 74.8 eV. From the TEM analysis performed on the 10 cycles sample (not shown), the deposited layer could not be distinguished, probably due to the fact that the film growth is still in the island regime (as shown by the island growth model) and no continuous ALD layer has been deposited on the surface. However, Fig. 6 shows a clear Al 2p peak, meaning that Al has already been deposited on the surface.

The O 1s spectra were fitted using a main peak at 531.8 eV, assigned to Al–O bonds. A small contribution from a second peak at 533.3 eV was also used for the fitting. Renault et al. [4] attributed such a peak situated at ΔE = 1.3–1.4 eV higher in energy than the main O 1s peak to Al-OH species. The presence of these species is consistent with the chemistry of TMA and H₂O [3,4,13]. TMA deposits on the surface in the form of Al(CH₃)₃ species. During the subsequent reactant exposure, H₂O reacts with the surface species, leading to the formation of Al-OH species, and CH₄ as a byproduct [3,4,13]. Non complete coverage of the Al–OH species during the next TMA exposure can lead to the incorporation of those Al–OH species in the film bulk. For a detailed understanding of the TMA + H₂O chemistry, the reader is referred to our previous work [13].

The Si 2p spectra presented in Fig. 6 show the chemical nature of the interface. For both samples, a clear doublet peak is situated at 98.9 eV (Si 2p₃/₂: 98.84 eV, Si 2p₁/₂: 99.47 eV), which is attributed to elemental Si. This shows that the depth of the analysis reaches the Si substrate, for the 10 and 50 cycles samples. A second peak is situated at 102.3 eV (Si 2p₃/₂: 102.04 eV, Si 2p₁/₂: 102.67 eV), for both samples, to
a $\Delta \varepsilon = 3.4$ eV from the Si$^0$ peak. This $\Delta \varepsilon$ value assigns this peak to Si of higher oxidation states, such as Si$^{3+}$ and Si$^{4+}$. In Fig. 6, this peak has been fitted by a doublet peak. However, different deconvolution schemes have been presented in the literature. By using the data treatment of Renault et al. [4], a peak at $\Delta \varepsilon = 3.01$ eV is found in our results, between the Si$^{4+}$ and Si$^{2+}$ peaks. This peak has a $\Delta \varepsilon$ that is too high to be assigned to Si$^{3+}$, and has previously been attributed to Al-silicate bonds by Renault et al. [4] This analysis concludes in the existence of multiple oxidation states of Si at the interface, including Si$^{3+}$, as well as to the presence of Al-silicates [4].

In order to study the elemental composition along the film depth, probing of Al, Si, and O species was performed by EDX on TEM cross sections. Measurements were performed along a straight line perpendicular to the sample surface, starting from the Si substrate and the obtained elemental profiles, excluding carbon, are shown in Fig. 7 for samples after 5, 20 and 200 ALD cycles. In order to study the passivation efficiency of the Si substrate pre-treatment, the EDX measurements along the film depth are also shown for the Si substrate without Al$_2$O$_3$ deposition in Fig. 7. Although this analysis is qualitative, it provides valuable insight for the evolution of the film and of the interface.

A very small rise on the O counts is detected on the Si surface (interface between Si substrate and C capping layer), for the substrate sample without deposition (Fig. 7a). This shows that the HF cleaning of the substrate removes the majority of surface oxides, leaving the surface H-terminated. The Si–H surface is passivated towards oxidation. Frank et al. [30] showed that the Si–H surface does not react with deuterated water, D$_2$O, even after repeated D$_2$O exposures [30]. They report a weak O presence on H-terminated Si(100) substrates, attributed to defect sites (Si–OH) remaining on the surface after the substrate cleaning due to the higher atomic roughness of the Si(100) surface [30]. Halls et al. [35] performed theoretical studies using DFT calculations on the H-terminated Si surface reactions with TMA and H$_2$O [35]. Their results confirm the low reactivity of the surface towards both reactants.

We therefore assign the small amount of detected O on the surface to such surface defect sites, like O bridges or Si–OH groups that have not been appropriately removed, or to SiO$_x$ formed after the sample exposure to air. The ALD nucleation during the first ALD cycles is reported to take place on such defects [16,17,30]. Our island growth model, fitted to the XRR measurements, estimates the surface concentration of those defects at 0.08 groups/nm$^2$. The ALD film starts forming on those defects. Then, subsequent deposition of Al on the surface catalyzes further Al$_2$O$_3$ deposition on nearby sites, as well as localized substrate oxidation, under and around the deposited Al$_2$O$_3$ [30,31].

This effect is seen on the Al, O, Si profiles on a 5 ALD cycle Al$_2$O$_3$ sample on Fig. 7b. In this case, between the Si substrate and the C layer, a clear peak on the O counts is observed, together with a small peak of Al. The presence of Al was also detected by XPS on a 10 cycle Al$_2$O$_3$ sample (Fig. 6). These results show that after 5 cycles, only a very small amount of Al has been deposited. This is consistent with the island growth model results and XRR measurements. After 5 cycles, the film deposition is still in its nucleation period and only small Al$_2$O$_3$ islands are deposited. However, even on the 5 cycle sample (Fig. 7b), the O peak is more significant than on the substrate sample (Fig. 7a). Starting from the Si substrate and moving to the C layer, we notice that the O

counts increase before the appearance of Al. This is attributed to the oxidation of the Si substrate, with an oxidation of the Si substrate under the Al2O3 deposition. However, it is not evident if this oxidation is inherent to the ALD process or if it is due to subsequent oxidation after the sample exposure to air. In both cases, this result shows that the Al deposition enhances Si oxidation, even at low Al surface concentration [30,31]. Frank et al. [30] also showed that after the first TMA pulse, subsequent D2O exposures lead to subsurface oxidation of Si [30]. By using the full width at half maximum (FWHM) of the element count peaks, we can estimate the total thickness of the oxidized layer at ~1.93 nm, of which ~1.63 nm consist of SiOx with no traces of Al, while the thickness where Al was traced is ~0.3 nm. These values show a slightly higher thickness of the oxidized layer than in Table 1.

Fig. 7c shows an Al2O3 sample deposited with 20 ALD cycles. The clear Al and O peaks in the profile are due to the deposition of Al2O3. Our island growth analysis shows that after 20 cycles, the growth regime is near the end of the island growth regime; however non continuity of the film was still predicted. By using the FWHM of the element count peaks, we deduce a region of ~1.5 nm, where only Si and O species are present, thus the formation of a SiOx layer. A ~0.7 nm region, where Si, O and Al species are all present, then is detected before the Al2O3 layer. This region can consist of Al-silicates or SiOx and AlOx. The presence of Al-silicates has also been reported before [4], and is one possible conclusion from the XPS analysis of the present work (Fig. 6). The total thickness of the interface containing Si is 2.2 nm, slightly higher than the one measured by TEM (Table 1).

The proposed mechanism for the Si oxide formation is the diffusion of O species from the deposited Al2O3 film [29], leading to Si oxidation. However, the reaction of H2O with surface Si groups during the island growth where the surface is not fully covered by the ALD film, catalyzed by the presence of Al [30,31], has also been suggested as a mechanism for the interfacial oxide growth [24,30]. Naumann et al. [24] reported that the OH groups formed during the initial island growth, lead to the formation of SiOH species. These species lead to further substrate oxidation after further increase of the ALD cycles. Xu et al. showed that by using a long exposure to TMA prior to ALD deposition, the interfacial Si oxide thickness is strongly restricted due to the covering of a larger fraction of the surface by Al species. The diffusion of O through the ALD layer is also a possible source of oxidation, which is however limited as the ALD film continues to grow due to the presence of Al2O3 as a diffusion barrier. Thus, oxidation by H2O and surface OH groups of the non-covered Si surface is restricted. As shown by Halls and Raghavachari [35], although the overall reaction between the ALD reactants and Si–H surface species is thermodynamically possible, the reactivity
is very low due to the high energy barrier required. Xu et al. [27,28] use a very long (3600 s) TMA exposure of the Si–H surface prior to deposition. Such a long exposure may be long enough for the reactants to react and deposit on the surface, covering a large fraction of the surface, thus restricting the induction period. However, for industrial applications, performing such exposures is challenging and costly, as processing time is highly increased and deposition takes place on all the reactor walls. Furthermore, the duration of the reactor purging, needed to ensure that no TMA is left in the chamber before starting the ALD process, would be extremely long. In our case, the exposure times are in the order of ms, and more than $10^5$ times smaller than in the case of Xu et al. [27,28] Hence, the reactions between the ALD reactants and the Si–H surface do not occur. The ALD reactants deposit only on surface defect sites. During subsequent cycles, the ALD reactants deposit preferentially on and around already deposited material, leading to island growth.

The EDX elemental profiles for the sample deposited using 200 ALD cycles shown in Fig. 7d, reveal the several nm thick Al$_2$O$_3$ film. Within the bulk of the Al$_2$O$_3$ film, a uniform Al and O concentration is measured by quantitative analysis (not shown), with a Al/O ratio close to the Al$_2$O$_3$ stoichiometry.

In the 5 and 20 cycles samples, the O peak is present even before the appearance of Al in the interface. This is not the case for the 200 cycle sample, where Si, O and Al species are present all along the interface. For the 5 and 20 cycles samples, the Al$_2$O$_3$ film may not be continuous and a part of the Si surface is directly exposed to atmospheric O, and thus oxidized. Therefore, the 20 nm thick Al$_2$O$_3$ film deposited for the 200 cycles sample serves as an effective diffusion barrier against O diffusion through the layer and prevents further Si oxidation by ambient air. Using the FWHM of the count peaks, we deduce a 1.2 nm interface, containing Si, O and Al. This value is smaller than the one measured by TEM (Table 1).

ToF-SIMS allows detailed investigation of the chemical composition of the film along its depth. Fig. 8 shows the elemental profile of the 200 cycles sample from the surface to the substrate. The SIMS analysis shows a uniform concentration profile for Al and O species in the core of the film, where no Si is detected. This confirms that during the stable ALD regime, the Al$_2$O$_3$ film is deposited with...
constant composition during each cycle. The surface is regenerated after the end of each ALD cycle, and the deposition process is repeated.

When the sputtering reaches the interface, the AlO and O counts decrease, until the Si substrate is reached, where AlO and O are no longer detected. The Si signal has the opposite behavior: Si counts start to increase at the same sputtering time where the AlO and O counts decrease, until the Si substrate is reached where the Si counts remain constant. The behavior of Al counts is different since they start to decrease when sputtering reaches the interface, as in the case of AlO and O. Then, the Al counts increase exhibiting a small peak in the interface, before decreasing to zero in the Si substrate region. This leads to the distinction of two regions in the interface: an Al depleted region at the top of the interface, closer to the core of the ALD film, and an Al enriched region, in the interface. The different behavior of the Al and AIO depth profiles within the interface witnesses a possible different chemical environment of Al within the interface showing that Al could be present in the interface in states different from Al2O3, such as Al-silicates. Gossel et al. [25] also performed SIMS characterizations on ALD deposited AlOx on H-terminated Si. They observed a similar behavior for the Al and OH species at the interface. After annealing in N2 at 800 °C and 1000 °C, they observed a small peak, this peak is attributed to Al2O3 from XPS (Fig. 6) showed a small peak that has previously been assigned to Al2O3 in the Si substrate region. This leads to the formation of SiOH groups during the island growth regime [24].

The SiOH groups are formed during the island growth regime that takes place during the first cycles of deposition. The mechanism for their formation could be the reaction of Al2O3 with Si surface species, which are non-fully covered by Al species during the island growth.

4. Conclusions

In this work, the ALD of Al2O3 films from TMA and H2O was studied on H-terminated Si (100) substrates, in a commercial reactor with the purpose to thoroughly investigate the initial film deposition evolution and interface formation. A series of samples using a different number of ALD cycles were deposited at 300 °C. The films and their interface with the substrate were characterized by XRR, TEM, BF-STEM, XPS, EDX and ToF-SIMS. A geometrical island growth model based on the work of Nilsen et al. [20] was used to reproduce the nucleation and growth steps during the first cycles. The model succeeded in representing the Al2O3 thickness evolution during the first ALD cycles, without involving the modelling of surface reactions. This approach showed that the evolution of the film growth can be explained by the geometric aspects of growth, without assuming an increasing surface reactivity during the first ALD cycles. It allowed the estimation of the surface concentration of defect sites, such as Si-OH and O bridges on the initial Si surface as close to 0.08 groups/nm2 and revealed that 25 ALD cycles are needed to achieve film continuity.

Concomitant results by TEM, BF-STEM, XPS, SIMS and EDX also showed that an interfacial layer was formed between the Al2O3 film and the Si substrate. This layer consists of oxidized Si in various oxidation states, while Al is also present, suggesting the presence of Al2O3 and Al-Silicates. In agreement with the reported results, the interfacial layer formation starts with the Al2O3 film during the first cycles. The mechanisms involve Si oxidation during the first cycles, when island growth takes place, and the surface is not fully covered by the Al2O3 film. Although this oxidation was highly restricted for the H-terminated Si surface, the presence of Al on the surface catalyzes Si oxidation, and thus the interfacial layer formation. This oxidation could occur through the formation of SiOH groups during the island growth. These SiOH groups could be formed from the reaction of OH species on the deposited islands with non-covered Si on the surface. SIMS results validated the presence of SiOH groups in the interface, thus further consolidating this assumption. Once the whole surface is covered by the ALD film, the interfacial oxide layer may continue to grow due to interdiffusion of O species through the layer. This interdiffusion has been assigned to bulk defect species, present in the form of AlOH, facilitating the oxygen diffusion.

These results can serve as guidance towards the research of adequate surface pre-treatment techniques for silicon substrates, aiming to enhance their surface reactivity towards the ALD reactants, and restrict silicon oxidation. The development of such pre-treatments will pave the way to successfully produce continuous ALD layers with thicknesses down to 3 nm and abrupt interfaces with Si, for future nanoelectronics.
